

Object-Oriented Programming

Professor: Suman Saha

Abstract Data Types

Primitive types: values and operations on values

User-defined types: records, lists, ...

Focus on values

ADT: defined by a set of operations on a type

Focus on operation

Stack is a type with `new`, `pop`, `push`, `empty` ...

Internal representation is less relevant

Classifying Operations

Creators: create new objects of type

Producers: create new objects from old ones

Mutators: change objects, e.g., `list.add(n)`

Observers: take objects of ADT and return
objects with different type, e.g., `list.size()`

ADT Examples

int

Creators: numeric literals $1, 2, 3, \dots$

Producers: arithmetic operations $+, -, *, /, \dots$

Observers: comparison operators $==, !=, <, >$

Mutators: none (immutable)

List

Creators: `ArrayList`, `LinkedList`, ...

Producers: `Collections.unmodifiableList()`

Observers: `size()`, `get()`

Mutators: `add()`, `remove()`, ...

ADT Examples

String

Creators: `String()`, `String(char[])`

Producers: `concat()`, `substring()`, ...

Observers: `length()`, `charAt()`, ...

Mutators: none (immutable)

OOP Terminology

Class: *a richer version of ADT*

Object (Instance): a variable of a class (a
value of a type)

Field: variable in a class

Method: operation in a class

Object-Oriented Programming

Key elements:

- Encapsulation
- Subtyping
- Inheritance

Encapsulation (Information hiding)

- Group data and operations in one place (typically, in one class)
- Hide irrelevant details (using visibility modifiers, such as *public*, *private*, *protected*)

Subtyping

```
interface Shape {  
    public double area();  
    public int edges();  
}
```

```
class Circle implements Shape {  
    double radius;  
    public double area() {return 3.14*radius*radius};  
    public int edges() {return 1};  
}
```

Inheritance

```
class ColoredCircle extends Circle {  
    private Color color;  
    ...  
    Color getColor {return color};  
    // methods area, edges are inherited from Circle  
}
```

Overriding

```
class DoubleCircle extends Circle {  
    public DoubleCircle(double r){super(r);}  
    public int edges {return 2};  
}
```

Subclass may redefine methods in super class

Object-Oriented Programming

Key elements:

- Encapsulation
- Subtyping
- Inheritance

How are these features implemented?

Running Example

Memory Layout (Fields)

An object has

- Fields (and ones from super class)

Circle object1:

DoubleCircle object:

ColoredCircle object:

```
foo (Circle s) {  
    s.radius;    // offset?  
}
```

Memory Layout (Functions)

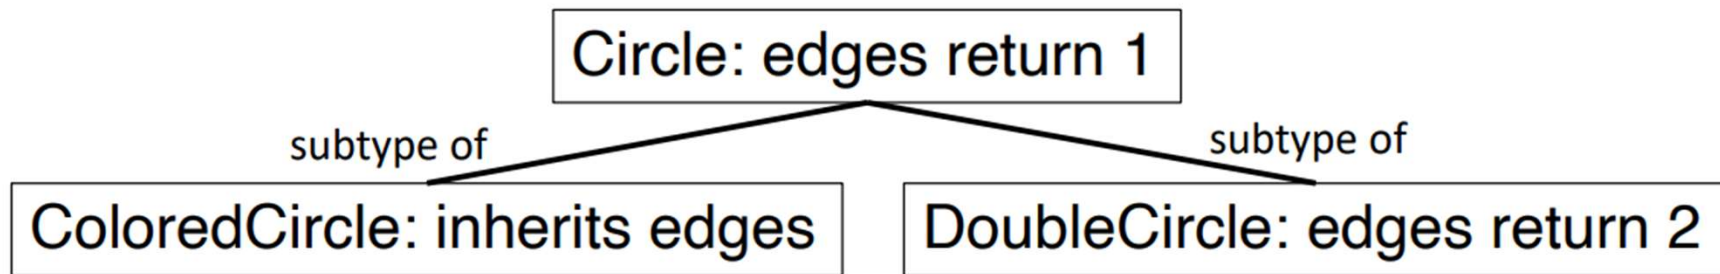

```
foo (Circle s) {  
    s.edges();    // which implementation?  
}
```

Static dispatch: s.edges() always returns 1

Dynamic dispatch: return value of s.edges() controlled by the type of s

Static Dispatch

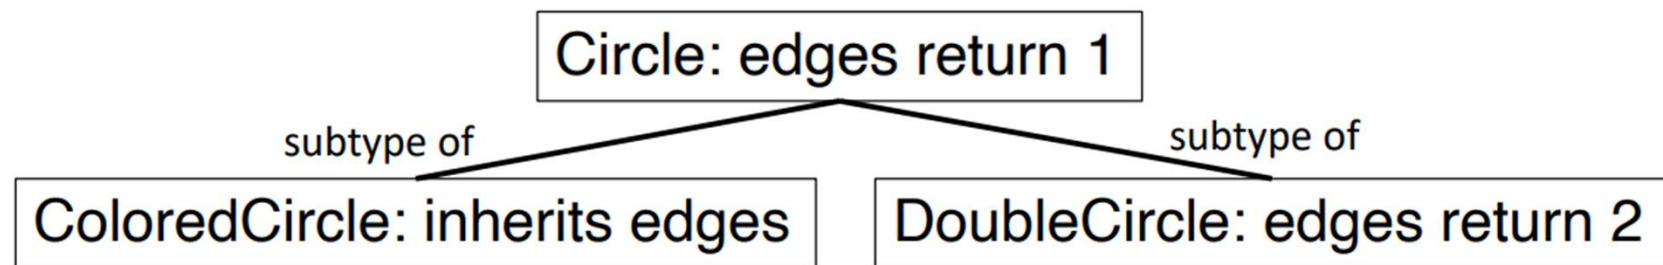

```
foo (Circle s) {  
    s.edges();    // which implementation?  
}
```

Dispatch to the implementation in class Circle

Hence, `s.edges()` always returns 1

Implementation: Static

```
foo (Circle s) {  
    s.edges();    // which implementation?  
}
```

The compiler can always tell which implementation at compile time (e.g., the edges method in class Circle)

Dynamic Dispatch

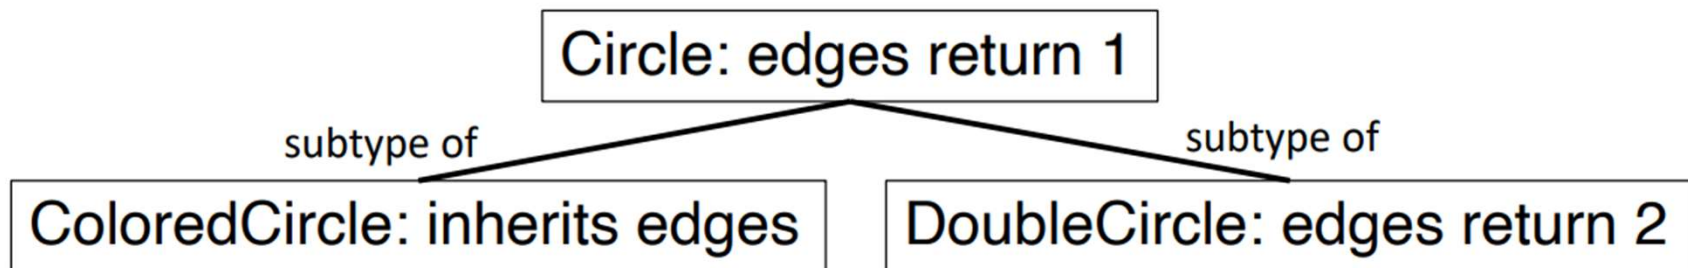

```
foo (Circle s) {  
    s.edges();    // which implementation?  
}
```

Dispatch to the implementation based on the type of the object s

Hence, `s.edges()` returns 2 when `s` is an object of class `DoubleCircle`

Implementation: Dynamic

```
foo (Circle s) {  
    s.edges();    // which implementation?  
}
```

The compiler does not know the type of s. How can it dispatch the method call to the correct implementation?

Trivial Memory Layout

An object has

- Fields (and ones from super class)
- Methods (and ones from super class)

Circle object1:

radius
edges: binary area: binary

Circle object2:

radius
edges: binary area: binary

DoubleCircle object:

radius
edges': binary area: binary

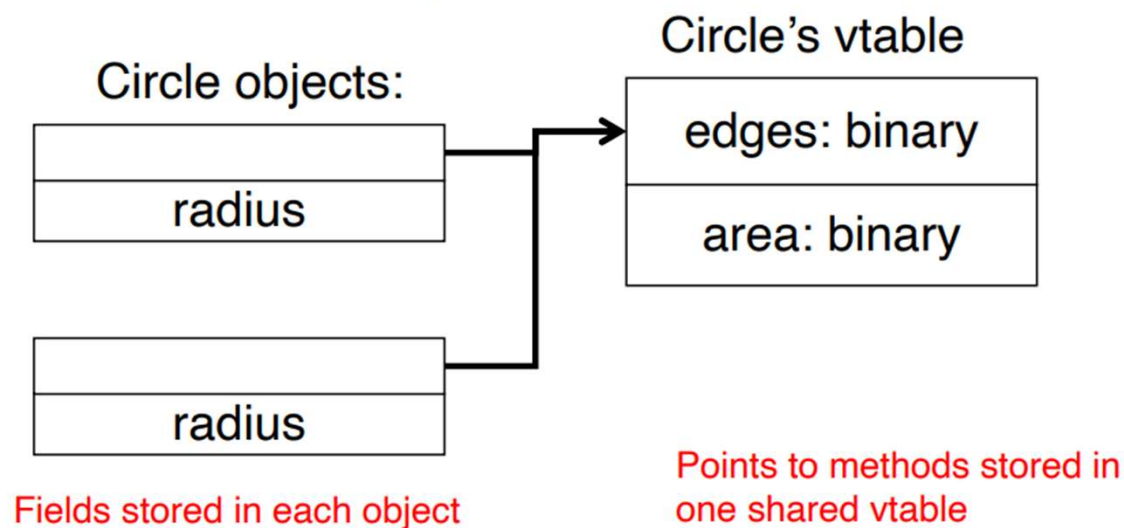

Issues: each object has a copy of impl. code (waste space)
polymorphic functions need to distinguish different
layouts of classes (to find method offset)

Virtual Table (vtable)

- Tentative design

A (shared) table containing method binaries

To save memory: one table per ***Class***

Virtual Table (vtable)

- Tentative design

A (shared) table containing methods

Override?

```
foo (Circle s) {  
    s.area(); // code has different offsets  
}
```

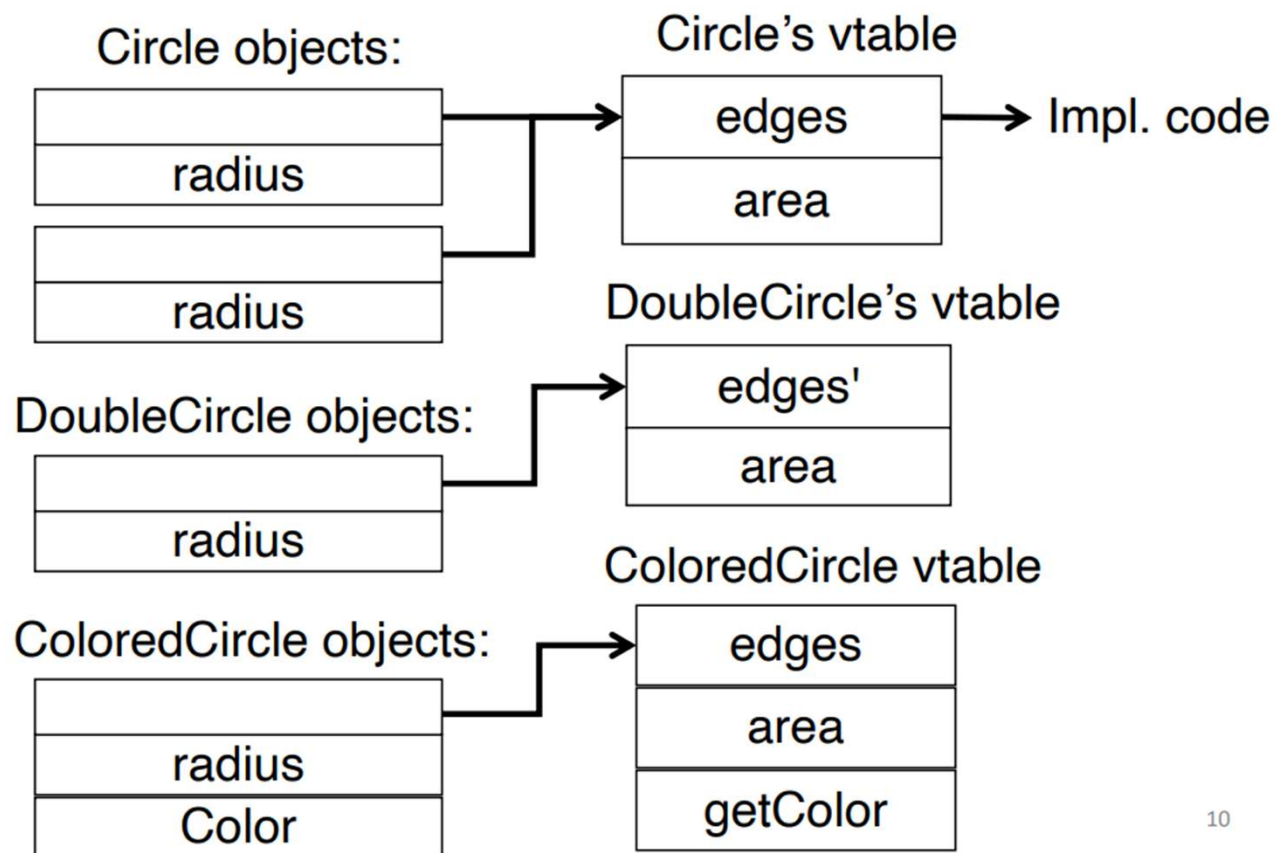

Issue: foo is compiled to different binaries
with different offsets for different types of s

Virtual Table (vtable)

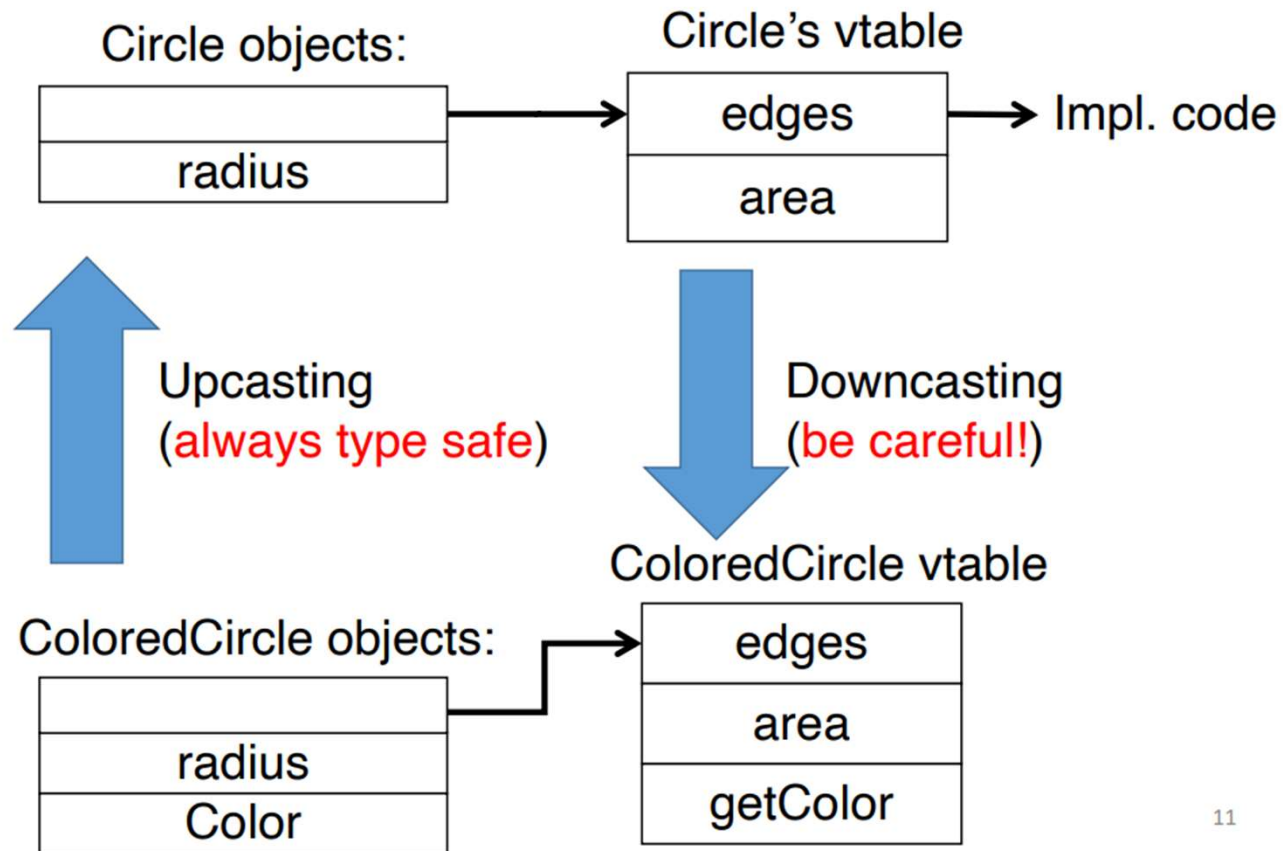

A (shared) table containing **pointers to methods**

Virtual Table (vtable)

Downcasting/Upcasting

Member Lookup: Case 1

When s is an object of class Circle

```
foo (Circle s) {  
    s.radius;  
    s.area();  
    s.edges();  
}
```

```
foo (Circle s) {  
    vt = *this;  
    *(this+4); //value of radius  
    call *(vt+4); // method area  
    call *vt; // method edges  
}
```

s.edges returns 1

Member Lookup: Case 2

When s is an object of class ColoredCircle

```
foo (Circle s) {  
    s.radius;  
    s.area();  
    s.edges();  
}
```

```
foo (Circle s) {  
    vt = *this;  
    *(this+4); //value of radius  
    call *(vt+4); // method area  
    call *vt; // method edges  
}
```

s.edges returns 1
Upcasting is type safe

Member Lookup: Case 3

When s is an object of class DoubleCircle

```
foo (Circle s) {  
    s.radius;  
    s.area();  
    s.edges();  
}
```

```
foo (Circle s) {  
    vt = *this;  
    *(this+4); //value of radius  
    call *(vt+4); // method area  
    call *vt; // method edges  
}
```

s.edges returns 2

Dynamic Dispatch with VTables

```
foo (Circle s) {  
    s.radius;  
    s.area();  
    s.edges();  
}
```

```
foo (Circle s) {  
    vt = *this;  
    *(this+4); //value of radius  
    call *(vt+4); // method area  
    call *vt; // method edges  
}
```

One implementation
for all subtypes!

Static vs. Dynamic Dispatching

Methods are dynamic

```
foo (Circle s) {  
    s.radius;  
    s.area();  
    s.edges();  
}
```

```
foo (Circle s) {  
    vt = *this;  
    *(this+4); //value of radius  
    call *(vt+4); // method area  
    call *vt; // method edges  
}
```

Methods are static

```
foo (Circle s) {  
    *(this+4); //value of radius  
    call Circle.area; // not in vt  
    call Circle.edges; // not in vt  
}
```

Cost of Dynamic Dispatch

Dynamic dispatch has costs, but is better for extensibility

In C++: static by default, except the `virtual` methods

In Java: dynamic by default, expect the ones that cannot be overridden (e.g., `final` and `static` methods)

In Python: all methods use dynamic dispatch
